Abstract

Deep learning has been introduced in the previous century for artificial intelligence program, and in recent years, it has risen strongly because of improvements in the computation performance. It has been applied to solve problems in different domains such as computer vision, speech recognition, or languages translation. Among different types of deep learning architectures, Convolutional Neural Networks have been most often used in computer vision for image classification, object recognition, or key points detection and they have brought amazing achievements. In this work, we propose a new Convolutional Neural Network model based on composition of elementary blocks of layers to predict key points (landmarks) on 2D anatomical biological images. Our proposed model has been trained and evaluated on a dataset including the images of 5 parts of 293 beetles. During the experiments, the network has been tested in two ways: training from scratch and applying fine-tuning process. To lead the pre-training step, a large public dataset of keypoints on human faces has been used. The obtained parameters have been then inserted to re-train the model on beetle's images. The quality of predicted landmarks is evaluated by

comparing the coordinates distance between predicted landmarks and manual ones which have been set by biologists. The final results have been delivered to biologists and they have confirmed that the quality of predicted landmarks is statistically good enough to replace the manual landmarks for most of the different morphometry analyses.

Keywords: Deep learning, CNN, fine-tuning, landmarks

1. Introduction

In recent years, deep learning which is a part of machine learning is known as a solution for difficult tasks in different domains[1]. Computational model of deep learning is composed of multiple layers to learn data representation. Each layer extracts the representation of input data which comes from the previous layers, then it will compute a new output to the next layer. In a deep learning model, each layer may contain different number of nodes, called *neurons* which have been inspired from the biological neural system [2]. Currently, deep learning has many kinds of variant architectures and each of them has found success such as: Deep Neural Network (DNN) to solve classification or data analysis problems[3, 4]; Convolutional Neural Network (CNN) in computer vision [5, 6, 7]; Recurrent Neural Network (RNN) on time sequences analysis [8, 9, 1, 10]. All of them have exhibited impressive performance comparing to more classical methods. Considering deep learning architectures, CNN is a specific one for pre-processing data which have grid topology, for examples, time series (1-D), 2D and 3D images, or video. From the first architecture [5] until now, many CNN models have been proposed and have succeeded in different tasks of computer vision such as image classification [5, 6, 7], object recognition [7, 11, 12], and key points detection [13, 14, 15, 16].

In computer vision, key points detection is an important field. In this field, algorithms try to find the key points , called Points of Interest (PoI) or land-

marks through images. The landmarks are considered as the points in the image that are invariant when the scene changes e.g. by some perspective projections. In biology, the landmarks are most often manually annotated on digital images
25 by biologists. Depending on the objective of work and the studied object, the number of landmarks may be different and their positions can be defined along the outline of the object or inside the object. From landmarks coordinates, it is possible to extract object features and to apply measure, for examples, to detect human face [14], human pose [17] or measures of an organism anatomy.

30 In this work, we propose a new composition of layers for a CNN architecture, Elementary Blocks Network (EB-Net), to predict the landmarks on biological species images. This model has been trained on a dataset of 5 parts of 293 beetles images: pronotum, head, elytra, left and right mandible. We have also designed a specific procedure to augment our dataset because several hundred images are
35 usually considered as a modest number to apply deep learning methods. Finally in order to boost the prediction we have applied transfer-learning procedure with the help of a public human face database and fine-tuned our parameters model. The biologists have asserted that at the end of this process, the predicted landmarks were statistically speaking good enough, in most of the cases, to
40 replace the manual landmarks.

This paper is organized as followed: Section 2 presents the related works about deep learning and setting of landmarks on 2D images. Section 3 describes the method to augment our dataset. Section 4 explains the design of new network model. The first experiments of the network on each dataset are
45 presented in Section 5, and the last section delivers all the final results including improvements provided by the fine-tuning procedure.

2. Related works

In the middle of the previous century, deep learning has been introduced by Lecun [1] as a method for artificial intelligence applications. However, several
50 problems appeared in order to take into account real-world cases because of the limitation of the memory size or computing power. Nowadays, huge improvements of computing capacities, both in memory size and in computing time with GPU programming, have opened a new perspective for deep learning. In recent years, deep learning architectures have achieved remarkable accomplishments in
55 many domains such as computer vision [5, 6, 7, 11, 12, 18], speech recognition [4, 3], language translation [8, 9], natural language processing [1, 10, 19]. Especially in computer vision, deep learning, specifically with CNN, has been used to achieve difficult tasks in image analysis such as image classification, objects or key points detection.

60 2.1. Overview of Convolutional Neural Network

A CNN is a feedforward network which takes the information following from the inputs to the outputs. Currently, CNNs have many variations, but it generally consists of several types of layers, as, convolutional, pooling or fully connected layer. Fig. 1 shows an overview of CNN network which inputs directly
65 an image to several stages of convolutional and pooling layers. Then, the representation is feed into three fully connected layers. A dropout layer is inserted after the second fully connected layer to drop some nodes during the training process (blue nodes). Finally, the last fully connected layer gives output as the category label for the initial input image. This architecture could be seen as
70 the most popular one. Reader interested in order details could read the review of Gu et al. [20].

Figure 1: A CNN network for classification problem

2.2. State of the arts in deep learning and key points detection

LeNet [5] model is considered as the first architecture of CNN. LeCun et al. [5] have used it to classify the handwritten digits in cheques. LeNet exhibits a
75 standard architecture of a CNN which consists of 2 convolutional layers, pooling layers, followed by two fully connected layers. But to be applied to realistic problems, this model requires huge computation capacities and large amount of training data which were hardly available in the early 2000s. In the last ten years, the computing capabilities have drastically improved while, in the
80 same time, a huge amount of data became available, new models of neural networks appeared well adapted to this new environment. One of the first ones is AlexNet [6], which is similar to LeNet [5] but with a deeper structure: LeNet has 2 convolutional layers and 1 fully connected layer while AlexNet has 5 and 3, respectively. Furthermore, in AlexNet the activation functions have been changed
85 and dropout layers have been added to prevent the over-fitting. AlexNet won the famous ImageNet Challenge² in 2012. From the success of AlexNet, a lot of different models have been proposed to improve the performance of CNN, one can cite ZFNet [21], GoogLeNet [7], VGGNet [22], or ResNet-50 [23]. The main difference between these networks is that their architectures became deeper and

²This is a challenge where evaluates algorithms for object detection and image classification.

90 deeper by adding more layers, e.g. ResNet-50, which won the champion of ILSVRC 2015, is deeper than AlexNet around 20 times.

Besides classification or recognition of objects, CNNs have been also used to detect key points inside images. Liu et al. [13] have presented a method to predict the positions of functional key points on fashion items such as the
95 corners of neckline, hemline and cuff. Yi Sun et al. [14] have proposed a CNNs cascade to predict the facial points belonging to the human face. Their model contains several CNNs which are linked together in a list as a cascade. Three levels of the cascade are set to recognize the human face from the global to local view with the objective to increase the accuracy of predicted key points. In
100 the same topic, Zhanpeng Zhang et al. [15] have proposed a *Tasks-Constrained Deep Convolutional Network* to join facial landmarks detection problem with a set of related tasks, e.g. head pose estimation, gender classification, age prediction, or facial attribute inference. In their method, the input features have been extracted by 4 convolutional layers, 3 pooling layers and 1 fully connected layer
105 which is shared by multiple tasks in the estimation step. Shaoli Huang et al. [17] have introduced a coarse-fine network to locate key points and to estimate human poses. Their framework consists of the base convolutional layers shared by two streams of key point detectors: the first stream, named coarse stream, includes 3 detector branches (3 stacks of Inception modules [7]) which are used
110 to focus on capturing local features and modeling spatial dependencies between human parts. The second one, named fine stream, receives the features which are concatenated from the coarse stream and provides accurate localization. Cintas et al. [16] have introduced an architecture which is enable to recognize 45 landmarks on human ears. Their model includes a structure with 2 convolutional layers, 1 pooling layers, and 1 dropout layer to extract the features. This
115 structure is repeated 3 times and is followed by 3 fully connected layers. In the

same context of key point detection, we have developed a CNN to automatize landmarks prediction on beetle's anatomies but before to describe it, we will present the augmentation procedure that we have defined for our dataset.

120 3. Data augmentation

From AlexNet period to ResNet-50, the obtained success stories [6, 23] have proved that CNN models produce better results on a large dataset but to use this technique, the size of dataset remains a bottleneck and our own some hundred of images are considered as modest for these models. So, it is important to be
125 able to provide a large dataset in order to learn more cases and improves the learning ability of the network. Unfortunately, in some application domains as this work in biology, providing a large dataset is too costly. For this reason, one way to solve this problem is to create misshapen data from real data and to add them to the training set. Most often in image processing, dataset augmentation
130 uses operations like translation, rotation or scaling which are well known to be efficient to generate new version of existing images. However, this kind of operations are not useful in our case because the analysis of images by CNN (convoluted) are usually invariant to translation or rotation. So, we preferred to rely on method changing color space values to obtain misshapen images.

135 Our image set is in RGB color map, the first procedure consists of changing the value of one color channel of the three channels in the original image to generate a new image. A constant value is sampled in an uniform distribution $\in [1, N]$ to obtain a new value caped at 255. For example, Fig. 2 shows the three images which are generated when a constant $c = 10$ is added to each channel
140 of an original image. Following this way, we can generate three new versions of only one image.

In the second procedure, each channel is considered separately and one gray

Figure 2: A constant $c = 10$ has been added to each channel of an original image

image is generated for it (Fig. 3). Consequently, we obtain 3 new images (single channel) from an original one. At the end of the process, 6 versions of an original
 145 image are made. In total, the new data set contains $293 \times 7 = 2051$ images for each anatomical part of beetle (an original image and six misshapen ones).

Figure 3: Three channels (red, green, blue) are separated from original image

4. Network architectures designing

As we have presented previously, several CNN architectures are available from literature and tools libraries. It is always possible to adapt them to a
 150 specific application by changing the parameters values or by modifying the arrangement of layers. Indeed, several trials have been achieved before to obtain a

satisfying model dedicated to landmarks estimation. In this section, we present three versions of the model that we have designed to solve this task. As usual, we have combined the classical layer types to build the model, i.e., convolutional, maximum pooling, dropout, and full-connected layers.

The first architecture has been a very classical one (Fig. 4). It receives an input image with the size of $1 \times 192 \times 256$, then it is composed by 3 repeated structures of a convolutional (CONV) layer followed by a maximum pooling (POOL) layer. In most of CNNs, the parameters of CONV layers have been set to increase the depth of the feature maps from the first to the last layer. This is done by setting the number of filters at each CONV layer. In this first model, the depths of the CONV layers increase from 32, 64, to 128 and with different size of the kernels: 3×3 , 2×2 and 2×2 , respectively. Inserting POOL layers after a convolutional layers is usually done. The POOL layer progressively reduce the spatial size of the representation, reduce the number of parameters, computation in the network, and also to prevent over-fitting. The operations of POOL layers are independent for each depth slice of their inputs. In our model, we have used the most common form for one POOL layer: a filter with size of 2×2 and a stride equal to the size of filter have been applied. At the end of the model, 3 FC layers have been added to extract the global relationship between the features and to proceed the outputs. The first two FC layers have been applied the activation functions to make sure these nodes interact well and to take into account all possible dependencies at the feature level. The outputs of the FC layers are 500, 500 and 16. The output of the last FC layer corresponds to the coordinates (x and y) of 8 landmarks which we would like to predict on pronotum part. Nevertheless, the obtained results with this architecture has not been considered good enough to continue to use it. One of the main problems is the presence of over-fitting during the training process (Detailed results will

be discussed in Section 5).

Figure 4: The architecture of the first model

180 The second model has kept the same architecture of the first model but the number of output of the two FC layers has been increased to 1000. Increasing the value at FC layers could allow to get more features from CONV layer without requirements of computing resources. However, the obtained results remained not satisfying, it will be discussed also in the result section (see Section 5).

185 To build the third architecture, we have defined the *Elementary Block* (EB). An EB is defined as a sequence of 1 CONV (C_i), 1 maximum POOL (P_i) and 1 dropout (D_i) layers (Fig. 5). The dropout layer has been added to prevent overfitting by adding a step to remove some nodes. This has significantly reduced overfitting and over performed the other regularization methods [24].

Figure 5: The layers in an elementary block. It includes a CONV layer (orange), a maximum POOL layer (yellow) and a DROP layer (green).

190 Fig. 6 illustrates the structure of the third architecture. For our purpose, we have assembled **3 elementary blocks** which are the main components of **EB-Net**. The parameters for each layer in each elementary block are described

as below, the list of values follows the order of elementary blocks ($i = [1..3]$):

- CONV layers:

- Number of filters: 32, 64, and 128
- Kernel filter sizes: (3×3) , (2×2) , and (2×2)
- Stride values: 1, 1, and 1

- POOL layers:

- Kernel filter sizes: (2×2) , (2×2) , and (2×2)
- Stride values: 2, 2, and 2

- DROP layers:

- Probabilities: 0.1, 0.2, and 0.3

For the FC layers, FC1 and FC2 have 1000 outputs, the last FC layer (FC3) has 16 outputs. As usual, a dropout layer is inserted between FC1 and FC2 with a probability equal to 0.5.

Figure 6: The architecture of EB-Net

The core of CNN is training over iteration. There are many ways to optimize the learning algorithm, but gradient descent [25] is currently a good choice to reduce the loss in neural network. The core idea is to follow the gradient until reaching a minimum of the cost function. So, we have chosen gradient descent in the backward phase to update the values of learnable parameters. EB-Net is designed to use a learning rate initialize at 0.03 and to

stop at 0.00001, while the momentum is updated from 0.9 to 0.9999. The values are updated over training time to fit with the number of epochs ³ by applying parameters adjustment during the training. The architecture implementation has been written in Lasagne framework [26] in Python code. More
 215 information about the model can be obtained from the repository on GitHub:
https://github.com/linhle vandlu/CNN_Beetles_Landmarks

5. Experiments and results

This work is a part of a project about automatized morphology measurements. Fig. 7 presents an image example of each part in our dataset. In these
 220 parts, the left and right mandibles have been processed in previous work based on image processing techniques to work with segmentable images [27]. The choice to turn to deep learning methods for the three remained ones, which have been motivated by the high difficulty to segment them, as we can observed
 225 in Fig. 7 and consequently to apply more usual image processing methods. The pronotum was the first part we have analyzed with deep learning and the presented results mainly concern these images.

Figure 7: The image in each part of beetle. From left to right: pronotum, elytra, head, left and right mandible.

The networks have been trained in 5,000 epochs on Linux OS by using NVIDIA TITAN X cards. During the training, the images are chosen randomly
 230 from the dataset with a ratio of 60% for training and 40% for validation. For

³An epoch is a single pass through the full training set

each image of pronotum, a set of 8 manual landmarks are available. They have been set by biologists and are considered as the ground truth for the evaluation. In deep learning, many kinds of loss expressions can be considered depending on the class of problem solving by the network, we have considered Root Mean Square Error (RMSE) because it is usually used for regression problems where the outputs are not discrete values and it is the case of the predicted coordinates values of landmarks.

In order to predict landmarks for all pronotum images, we have applied *cross-validation* procedure to choose the test images, we call it *round*. For each round, we have decided to choose 33 images for testing step. The 260 remaining images are used as training and validation images. In order to predict landmarks for all available images, we did 9 rounds. Of course, this dataset has been augmented as described before to provide 1820 images for these 2 steps.

Figure 8: The losses (training and validation) of the models. The blue curve presents the RMSE errors of training process while green curve is the validation errors.

As it has been mentioned in Section 4, the first and the second architectures exhibit over-fitting behavior. Fig. 8 shows the different curves of the losses during training and validation steps. The blue curves present the RMSE errors of training process while green curves are the validation errors. Clearly, over-

fitting has appeared in the first model, e.g., training losses are able to decrease but validation losses are stable. In the second architecture (Section 4), there is
 250 no concrete change in the curves even the parameters of full-connected layers have been modified.

Fig. 9 illustrates the losses during the training of the last version, EB-Net, one can note that after several epochs, the two-loss values become close and the over-fitting disappears. Addition of Dropout sequence inside elementary
 255 block works well to prevent over-fitting and improves the accuracy of the model greatly.

Figure 9: The losses (training and validation) of EB-Net

Table 1 resumes the losses of 9 rounds when we trained EB-Net on pronotum images. Clearly, the training/validation losses among rounds are tiny and stable.

To evaluate the coordinates of predicted landmarks, the Pearson correlation
 260 metric between predicted and manual landmarks has been calculated for each dimension (x and y). Table 2 shows the obtained results. The average value of the coordinates correlation (both x and y) is in the first row, variance, minimum and maximum of correlation scores are given in the next rows. One can note

Round	Training loss	Validation loss
1	0.00018	0.00019
2	0.00019	0.00021
3	0.00019	0.00026
4	0.00021	0.00029
5	0.00021	0.00029
6	0.00019	0.00018
7	0.00018	0.00018
8	0.00018	0.00021
9	0.00020	0.00027

Table 1: The losses during training the third model on pronotum images

that the correlation is strongly positive in each case with a very small variance, proving that each individual coordinate is well predicted.

	X-dimension	Y-dimension
Mean	0.8116	0.9438
Variance	0.0020	0.0006
Min	0.7474	0.9063
Max	0.8577	0.9638

Table 2: Statistical indicators on Pearson correlation between manual and predicted landmarks

265

Standing on the side of the users, biologists would like to obtain an acceptable position of the landmark when they look at the images. So, the distances (in pixels) between manual coordinates and predicted ones have been calculated for all images. Then, the average distance for each landmark has been computed.

270

Table 3 shows the average distances by landmarks on all images of pronotum dataset. With the images resolution 256×192 , we can consider that an error of 1% (corresponding to 2 pixels) could be an acceptable error. Unhappily, our results exhibit average distance of 4 pixels in the best case, landmark 1 and more than 5 pixels in the worse case, landmark 6.

275

To illustrate this purpose, Fig. 10 shows the predicted landmarks on two test images. One can note that even some predicted landmarks (Fig. 10a) are

Landmark	Distance (in pixels)
1	4.002
2	4.4831
3	4.2959
4	4.3865
5	4.2925
6	5.3631
7	4.636
8	4.9363

Table 3: The average distances on all images per landmark on pronotum images.

close to the manual ones, in some case (Fig. 10b) the predicted ones are far from the expected results. So, the next step has been dedicated to the improvement of these results.

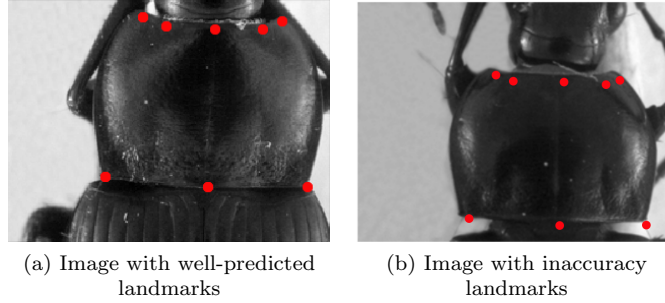

Figure 10: The predicted landmarks, in red, on the images in test set.

280 To analyze how to improve the results, we have studied the distribution of the distance between manual and predicted landmarks. Fig. 11 shows the distribution of the distances of the first landmarks (the best case) in pronotum images. The accuracy based on the distance in each image can be separated into three spaces: best results, the images having distance less than the average value (4 pixels): 56.66%; acceptable results, the images having the distance from the average value to 7 pixels (standard deviation error): 31.40%; and the images
285 which are clearly in error with the distance greater than 7 pixels: 11.94%.

Figure 11: The distribution of the distances on the best case (1st landmark).
The line present for the average values.

6. Improving results by fine-tuning

The results that we have just discussed, have been obtained by training EB-
 290 Net from scratch but training a network from scratch is not the only way to work
 in Deep learning. It is possible to initialize parameter values by extracted values
 from another experiment on another dataset. It is called transfer learning [28].
 In tranfer learning, the obtained parameters values of a model which have been
 used to solve a problem, are reused for other datasets [29] and potentially to
 295 solve another task. The name of this procedure is currently called **fine-tuning**.

Fine-tuning does not only replace and retrain the last layer of the model on
 the new dataset but also tunes the weights of a trained model by continuing
 the backpropagation. In this context, ImageNet [30], a well-known dataset with
 more than 100,000 images, has been used to train many famous CNN architec-
 300 tures such as AlexNet [6] or VGG-16 [22] with success. The pre-trained models
 on ImageNet have been then shared in deep learning community as a source to
 re-use features of ImageNet. Unfortunately, some preliminary tests have shown
 that re-using ImageNet features is not relevant for our application because land-
 marks dectection has a distinct difference from general object recognition, as
 305 mentioned in [31]. On another note, searching for landmarks is well defined in
 face recognition and facial key points detection and we can consider that this

application is similar to our problem. So, we have decided to train EB-Net on a facial key points dataset and then to transfer the trained parameters to fine-tune on beetle’s images.

310 6.1. Pre-train EB-Net on facial key points dataset

A **Facial Keypoints dataset** has been published for a competition on Kaggle community ⁴. It includes 2,140 human face images with the size of 96×96 . Each image contains 15 landmarks on the face: 6 landmarks for eyes, 4 landmarks for eyebrows, 4 landmarks for mouth, and 1 landmarks for nose tip.

315 Fig. 12 shows four face images in the dataset and the landmarks on each face.

Figure 12: Four face images in the dataset and ground truth position of the landmarks.

For the pre-training step, EB-Net has been trained with this dataset, the objective of this task has been to evaluate and to compare the effectiveness of EB-Net with other published results in the challenge. Basically, the layer’s parameters are the same than for training from scratch. We have just changed
 320 the image size of network model to 96×96 and the output number of the last FC layer to correspond to the waited number of landmarks (15 landmarks). For the hyper-parameters of model, the learning rate and momentum remained the same but the number of epochs has been changed to 10,000 instead of 5,000 to improve the parameters learning. After training, the obtained RMSE score is
 325 1.1464. This score is better than top 3 of the challenge.

⁴<https://www.kaggle.com/c/facial-key-points-detection>

6.2. Fine-tuning on beetle parts

The parameters obtained from this pre-training has been then transfered to continue the process with beetle images. The fine-tuning stage has been done by continuing the backpropagation to update the layers parameters. One can note
330 that, the images in Facial Keypoints dataset are squared, in order to respect this we have reduced the size of beetle’s images to 192×192 by cropping a background band. To declare this, the stride property of the first convolutional layer has been also modified from 1 to 2.

After finishing the fine-tuning process, EB-Net is used to predict the land-
335 marks on test images. To evaluate the accuracy of the model’s outputs, the distances (in pixels) between predicted and corresponding manual landmarks have been calculated again as their average distances. Tables 4 resumes the results on pronotum images: **From scratch** columns remind the previously average distances when EB-Net was trained from scratch; **Fine-tune** columns
340 present the new average distances after applying fine-tuning. The green and red values are respectively the best and the worst average distances. The results of elytra and head can be seen in Appendix A. First of all, the results have been clearly improved with the help of transfer learning for each landmark.

#LM	From scratch	Fine-tune
1	4.00	2.99
2	4.48	3.41
3	4.30	2.98
4	4.39	3.54
5	4.29	3.37
6	5.36	4.06
7	4.64	2.93
8	4.94	3.64

Table 4: Average distances comparison between training from scratch and fine-tuning on pronotum images

It is worth to note that average computing can hide different situations. So,

the distribution of the distances has been taken into account. Fig. 13 describes the distribution of distances of two examples cases: 1^{st} and 6^{th} landmarks. Clearly, with the help of fine-tuning, the distances have been decreased and more convergence to the mean value.

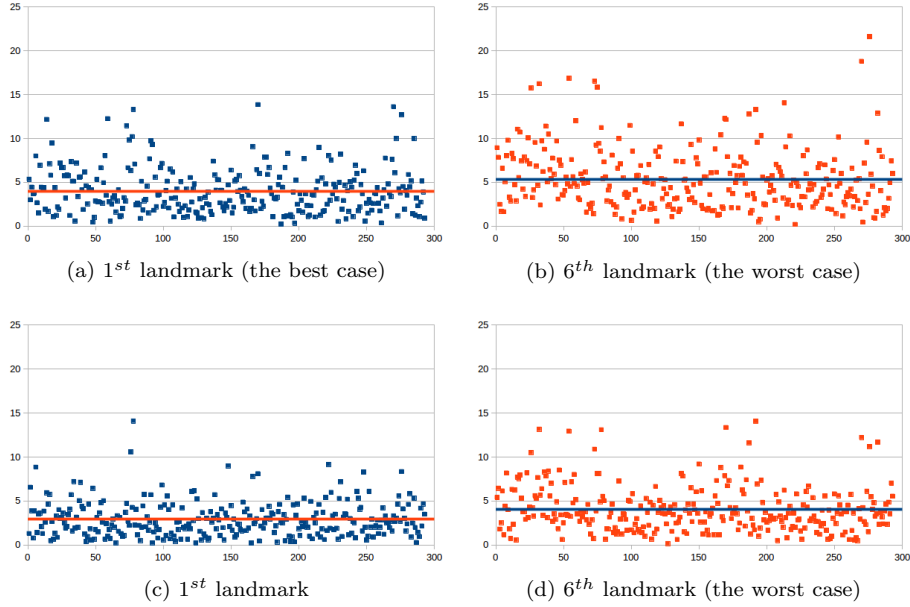

Figure 13: A comparison of distances distribution of the 1^{st} landmark and the worst case (6^{th} landmark) when applying two processes. The top/bottom line shows the distribution when applying training from scratch/fine-tuning. The lines in charts present for the average values.

Another way to characterize the distribution of the values can be given by standard error, median, minimum and maximum values. These statistical values are presented in Appendix B. From these tables, we can see the minimum and the maximum distances have a large range of values. However, the median values, which separate the distances set into two parts, are smaller than the averages values and they are very close to the minimum values and so far from maximum values. It confirms that almost all distances stay around the median values and the predicted landmarks are good enough to replace the manual ones.

Besides, the distribution of the distances on each landmark of each part have been taken into account in Appendix C. We can observe that most of distances are close to the mean and median values, only some exceptional cases are really far. Fig. 14 shows the predicted landmarks of fine-tuning process in one case of each part. The red points and yellow points represent for predicted and manual landmarks, respectively.

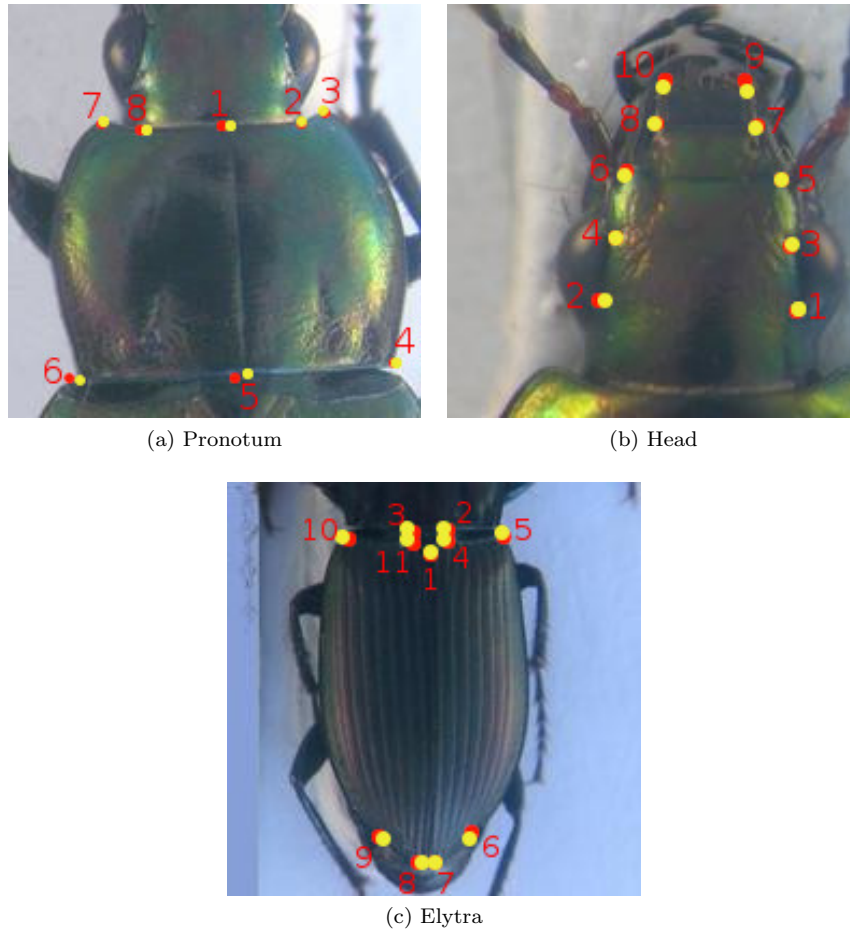

Figure 14: The location of predicted landmarks (red points) in one case of each part

The fine-tuning process has improved the results of the proposed architecture on both 5 datasets: left, right mandible, pronotum, elytra and head. All the

average distances have significantly decreased: $\approx 25.98\%$ on pronotum, $\approx 15.8\%$ on elytra, and $\approx 18.10\%$ on head part. Besides, if we consider a predicted landmark, which has the distance (from manual ones) less than mean value plus standard deviation, is acceptable, the accuracy of method on each part is **87.07%** on pronotum, **87.92%** on head, and **91.78%** on elytra.

We also have a comparison between the results of deep learning and early methods where we have applied image processing techniques to predict the landmarks [27]. Clearly, the result with fine-tuning has improved the location of estimated landmarks. Even the average distances obtained from scratch training are still higher but they are more stable than the results from the early method: most of the average distance(or landmarks) of left mandibles are less than the results of the early method, while the average distances are very close in the case of right mandibles.

7. Conclusion

In this work, we have presented a new CNN model, EB-Net, to predict key points - landmarks on 2D anatomical images of beetles. EB-Net model includes the repetition of 3 Elementary Blocks, followed by 3 fully connected layers. An elementary block is a sequence of 1 CONV layer, 1 maximum POOL layer and 1 Dropout layer. In order to augment the dataset size, we have generated new images by modification of color channels of the original images. The training step has been improved by using transfer learning from the a dataset of human facial keypoints.

The results have shown that using the convolutional network to predict the landmarks on biological images leads to satisfying results without need for time consuming human intervention (i.e. semi-automatic methods) or lots of pre- and post- processing of the digital images. The best set of estimated landmarks

has been obtained after a step of fine-tuning using the whole set of images that we have for the project, i.e. about all beetle parts. The quality of prediction allows using automatic landmarking to replace the manual ones.

In our case, the size of dataset is limiting. Therefore, we have applied image processing techniques to augment dataset. The predicted landmarks have been evaluated by calculating the distance between manual landmarks and corresponding predicted landmarks. Then, the average of distance errors on each landmarks has been considered.

Appendix A. Comparing the results between training from scratch and fine-tuning process

490

#LM	From scratch	Fine-tune
1	5.53	4.82
2	5.16	4.21
3	5.38	4.73
4	5.03	4.11
5	4.18	2.76
6	4.45	3.50
7	4.79	3.92
8	4.53	3.40
9	5.14	4.17
10	5.06	3.94

Table A.5: Average distances comparison between training from scratch and fine-tuning on head images

#LM	From scratch	Fine-tune
1	3.87	3.21
2	3.97	3.28
3	3.92	3.20
4	3.87	3.22
5	4.02	3.31
6	4.84	4.21
7	5.21	4.54
8	5.47	4.76
9	5.27	4.55
10	4.07	3.39
11	3.99	3.29

Table A.6: Average distances comparison between training from scratch and fine-tuning on elytra images

Appendix B. Statistic information on each beetle's part

Table B.7, B.8, and B.9 show the statistical values on each part. The green and red numbers represent the best and the worst values on each statistical indicators, respectively.

#LM	Mean	Standard Error	Median	Minimum	Maximum
