Abstract

Deep learning has been introduced in the middle of the previous century for artificial intelligence program, and in recent years, it has risen strongly because of improvements in the computation performance. It has been applied to solve problems in different domains such as computer vision, speech recognition, or languages translation. Among different types of deep learning architectures, convolutional neural networks have been most often used in computer vision for image classification, object recognition, or key points detection and they have brought amazing achievements. In this work, we propose a new convolutional neural network model based on composition of elementary blocks of layers to predict key points (landmarks) on 2D anatomical biological images. Our proposed model has been trained and evaluated on a dataset including the images of 5 parts of 293 beetles. During the experiments, the network has been tested in two ways: training from scratch and applying fine-tuning process. The quality of predicted landmarks is evaluated by comparing the coordinates distance between predicted landmarks and manual ones which have been set by biologists. The final results have been provided to biologists and they have confirmed that

the quality of predicted landmarks is statistically good enough to replace the manual landmarks for most of the different morphometry analyses.

Keywords: Deep learning, CNN, fine-tuning, landmarks

1. Introduction

In recent years, deep learning [1] is known as a solution for difficult tasks in different domains. It has been known as a part of machine learning domain. Computational model of deep learning is composed of multiple layers to learn data representation. Each layer extracts the representation of input data which comes from the previous layers, then it will compute a new output to the next layer. In a deep learning model, each layer may contain different number of nodes, called *neurons* which have been inspired from the biological neural system [2]. Currently, deep learning has many kinds of variant architectures and each of them has found success in such as: Deep Neural Network (DNN) to solve classification or data analysis problems[3, 4]; Convolutional Neural Network (CNN) in computer vision [5, 6, 7]; Recurrent Neural Network (RNN) on time sequences analysis [8, 9, 1, 10]. All of them have exhibited impressive performance comparing to more classical methods. In deep learning architectures, CNN is a specific network for pre-processing data which have grid topology, for examples, time series (1-D), 2D and 3D images, or video. From the first architecture [5] until now, many CNN models have been proposed and have succeeded in different tasks of computer vision such as image classification [5, 6, 7], object recognition [7, 11, 12], and key points detection [13, 14, 15, 16].

In computer vision, key points detection is an important field. In this field, algorithms try to find the key points (called points of interest (PoI) or landmarks) through images. The landmarks are considered as the points in the image that are invariant when the scene changes e.g. by some perspective projections. In biology, the landmarks are most often provided by the biologists.

25 Depending on the objective of work and the studied object, the number of
landmarks may be different, as well as their positions can be defined along the
outline of the object or inside the object. From landmarks coordinates, it is
possible to extract object characteristics and to apply measure, for examples, to
detect human face [14], human pose [17] or topology of objects in an organism
30 in biology.

In this work, we propose a new composition of layers for a CNN architecture
to predict the landmarks on biological species images. The proposed model
has been trained on a dataset of 293 beetles images. We have also designed a
specific procedure to augment our dataset because several hundred images are
35 usually considered as a modest number to apply deep learning methods. After
applying our model, the biologists have asserted that the predicted landmarks
which have been provided by our model, were enough good in most case to
replace the manual landmarks.

This paper is organized as followed: Section 2 discusses the related works
40 about deep learning and setting of landmarks on 2D images. Section 3 presents
the method to augment our dataset. Section 4 explains the design of new net-
work model. The first experiments of the network on each dataset are presented
in Section 5. In the last section, we present a technique to improve the results
of the proposed model: fine-tuning.

45 **2. Related works**

In the middle of the previous century, deep learning [1] have been introduced
as a method for artificial intelligence applications. However, several problems
appeared in order to take into account real-world cases because of the limita-
tion of memory size or computing power. Nowadays, huge improvements of
50 computing capacities, both in memory size and in computing time with GPU

programming, have opened a new perspective for deep learning. In recent years, deep learning architectures have achieved remarkable accomplishments in many domains such as **computer vision** [5, 6, 7, 11, 12], **speech recognition** [4, 3], **language translation** [8, 9], **natural language processing** [1, 10, 18]. Especially in computer vision, deep learning, specifically with CNN, has been used to achieve difficult tasks in image analysis such as image classification, objects or key points detection.

2.1. Overview of Convolutional Neural Network

A CNN is a feedforward network which takes the information following one direction from the inputs to the outputs. Currently, CNNs have many variations, but it generally consists of several types of layers, for examples, convolutional layer, pooling layer or fully connected layer. In which, convolutional and pooling layers are stacked together to convolve and to down-sample the inputs. Then, the fully connected layers are followed to achieve the output of the network from the application of a decision function.

Fig. 1 shows a classical example of a CNN network, it inputs directly an image to several stages of convolutional and pooling layers. Then, the representation is feed into three fully connected layers. A dropout layer is inserted after the second fully connected layer to drop some nodes during the training process (blue nodes). Finally, the last fully connected layer gives output as the category label for the input image. This architecture could be seen as the most popular one. Now, we will describe the different types of layers, readers familiar to term can jump directly to the next section.

Convolutional (CONV) layer is used as a feature extractor by applying some learnable weights (filters) on the input images. The image values are convolved with the filters in order to compute the new feature maps; then the convolved results are sent through a nonlinear activation before sending to the next layer.

Figure 1: A CNN network for classification problem

In CONV layer, the neurons are arranged into feature maps. All the neurons within a feature map have the same weights; however, different features maps
 80 within the same CONV layer have different weights so that several features can be extracted at each location of an input image.

Pooling (POOL) layer is mostly used to down-sampling the size of the input with the purpose to reduce the spatial resolution of the feature map and so to reduce the computation cost. Initially, it was a common practice to use average
 85 pooling to propagate the average of all the inputs to the next layer. However, in more recent models [6, 12, 19], maximum pooling function has been preferred. It propagates the maximum values of the inputs to the next one. Fig. 2 illustrates the differences between maximum and average pooling: Giving an input image of size 4×4 , if applying a filter with size of 2×2 and a stride of 2, if we apply to
 90 the yellow region an average pooling, the output will be 36.25 and a maximum pooling will return the value 122.

Dropout (DROP) [20] is a technique used to prevent over-fitting during the training. The term dropout mentions dropping some output units and their connections (incoming and outgoing) belonging to a layer in the network. The units
 95 are dropped randomly with a probability p . When applying dropout technique, the network becomes a collection of thinned networks [20]. So, training a neural network with dropout looks like training a collection of thinned networks. The

Figure 2: The results of different pooling

dropouts layers are most often placed after the fully connected layers, but it is possible to use them after the pooling layers to learn the most robust features possible.

Fully connected (FC) layer usually follows the group of convolutional and pooling layers to extract the abstract feature representations of the image. A CNN may have one or several FC layers. They interpret the feature representations (their inputs) and perform a function of high-level reasoning by applying the activation functions. In practice, the last fully connected layer produces the output of the network and choosing the activation function is depended on which kind of problem that network solves.

2.2. State of the arts in deep learning and key points detection

LeNet [5] model is considered as the first architecture of CNN. LeCun et al. [5] have used LeNet to classify the handwritten digits in cheques. LeNet exhibits a standard architecture of a CNN which consists of convolutional layers, pooling layers, followed by two fully connected layers. But to be applied to realistic problems, this model requires huge computation capacities and a large amount of training data which are not available at the early 2000s. In the last

115 ten years, as the capabilities to compute have been drastically improved and in
 the same time, a huge amount of data became available, new models of neural
 networks appear well adapted to this new environment. One of the first ones is
 AlexNet [6], which is similar to LeNet [5] but with a deeper structure: LeNet has
 2 convolutional layers and 1 fully connected layer while AlexNet has 5 and 3, re-
 120 spectively. Furthermore, in AlexNet the activation functions have been changed
 and dropout layers have been added to prevent the over-fitting. AlexNet won
 the famous ImageNet Challenge² in 2012. From the success of AlexNet, a lot of
 different models have been proposed to improve the performance of CNN, one
 can cite ZFNet [21], GoogLeNet [7], VGGNet [22], or ResNet-50 [23]. The main
 125 difference between these networks is that their architectures became deeper and
 deeper by adding more layers, e.g. ResNet-50, which won the champion of
 ILSVRC 2015, is deeper than AlexNet around 20 times.

Besides classification or recognition of objects, CNNs have been also used
 to detect key points inside images. Liu et al. [13] have presented a method
 130 to predict the positions of functional key points on fashion items such as the
 corners of neckline, hemline and cuff. Yi Sun et al. [14] have proposed a CNNs
 cascade to predict the facial points on the human face. Their model contains
 several CNNs which are linked together in a list as a cascade. Three levels of
 the cascade are set to recognize the human face from the global to local view
 135 with the objective to increase the accuracy of predicted key points. In the same
 topic, Zhanpeng Zhang et al. [15] have proposed a *Tasks-Constrained Deep
 Convolutional Network* to join facial landmarks detection problem with a set of
 related tasks, e.g. head pose estimation, gender classification, age prediction,
 or facial attribute inference. In their method, the input features have been ex-
 140 tracted by 4 convolutional layers, 3 pooling layers and 1 fully connected layer

²This is a challenge where evaluates algorithms for object detection and image classification.

which is shared by multiple tasks in the estimation step. Shaoli Huang et al. [17] have introduced a coarse-fine network to locate key points and to estimate human poses. Their framework consists of the base convolutional layers shared by two streams of key point detectors: The first stream, named coarse stream, includes 3 detector branches (3 stacks of Inception modules [7]) which are used to focus on capturing local characteristics and modeling spatial dependencies between human parts. The second one, named fine stream, receives features which are concatenated from the coarse stream and provides the accurate localization. Cintas et al. [16] have introduced an architecture which is enable to recognize 45 landmarks on human ears. Their proposed model includes a structure with 2 convolutional layers, 1 pooling layers, and 1 dropout layer to extract the features. This structure is repeated 3 times and is followed by 3 fully connected layers. In the same context of key point detection, we have developed a CNN to automatize landmarks prediction on beetle’s anatomies.

From AlexNet period to ResNet-50, the obtained success stories [6, 23] have proved that CNN models produce better results on a large dataset. To use this technique, the size of dataset remains a bottleneck. The next section turns to the description of the method we have designed to augment the size of the dataset.

3. Data augmentation

Most of deep learning algorithms are supervised learners. So, providing a large dataset enables to learn more cases and clearly improves the learnable of the network. Unfortunately, in some application domains as in biology, providing a large dataset is too costly. For this reason, one way to solve this problem is to create misshapen data from real data and to add them to the training set. Most often in image processing, dataset augmentation uses operations like

translation, rotation or scaling which are well known to be efficient to generate new version of existing images. However, this kind of operations are not useful in our case because the analysis of images by CNN (convoluted) are most often invariant to translation or rotation. So, we prefer to rely on method changing color space values to obtain misshapen images.

Our image set is in RGB color map, the first procedure consists of changing the value of one color channel of the three channels in the original image to generate a new image. A constant value is sampled in an uniform distribution $\in [1, N]$ to obtain a new value capped at 255. For example, Fig. 3 shows the three images which are generated when a constant $c = 10$ is added to each channel of an original image. Following this way, we can generate three new versions of only one image.

Figure 3: A constant $c = 10$ has been added to each channel of an original image

In the second procedure, each channel is considered separately and one gray image is generated for it (Fig. 4). Consequently, we obtain 3 new images (single channel) from an original one. At the end of the process, 6 versions of an original image are made. In total, the new data set contains $293 \times 7 = 2051$ images for each anatomical part of beetle (an original image and six misshapen ones).

Figure 4: Three channels (red, green, blue) are separated from original image

4. Network architectures designing

As we have presented previously, several CNN architectures are available from literature and tools libraries. It is always possible to adapt them to a specific application by changing the parameters values or by modifying the arrangement of layers. By the way, several trials have been achieved before to obtain a satisfying model dedicated to landmarks estimation. In this section, we present three versions of the model that we have designed to solve this task. As usual, we have combined the classical layer types to build the model, i.e., convolutional, maximum pooling, dropout, and full-connected layers.

The first architecture has been a very classical one (Fig. 5). It receives an input image with the size of $1 \times 192 \times 256$, then it is composed by three repeated structures of a convolutional (CONV) layer followed by a maximum pooling (POOL) layer. In most of CNNs, the parameters of CONV layers have been set to increase the depth of the feature maps from the first to the last layer. This is done by setting the number of filters at each CONV layer. In this first model, the depths of the CONV layers increase from 32, 64, to 128 and with different size of the kernels: (3×3) , (2×2) and (2×2) , respectively. Inserting POOL layers after a convolutional layers is usually done. The POOL layer

progressively reduce the spatial size of the representation, reduce the number of parameters, computation in the network, and also to prevent over-fitting. The operations of POOL layers are independent for each depth slice of their inputs.

In our model, we have used the most common form for one POOL layer: a filter with size of 2×2 and a stride equal to the size of filter have been applied. At the end of the model, three FC layers have been added to extract the global relationship between the features and to proceed the outputs. The first two FC layers have been applied the activation functions to make sure these nodes interact well and to take into account all possible dependencies at the feature level. The outputs of the FC layers are 500, 500 and 16. The output of the last FC layer corresponds to the coordinates (x and y) of 8 landmarks which we would like to predict on pronotum part. Nevertheless, the obtained results with this architecture has not been considered as good enough to continue to use it. One of the main problems is the presence of over-fitting during the training process (Detailed results will be discussed in Section 5).

Figure 5: The architecture of the first model

The second model has kept the same architecture of the first model but the number of output of the two FC layers has been increased to 1000. Increasing the value at FC layers could allow to get more features from CONV layer without requirements of computing resources. However, the obtained results remained not satisfying, it will be discussed in the result section (Section 5).

To build the third architecture, we have defined the *elementary block*. An elementary block is defined as a sequence of a CONV (C_i), a maximum POOL

(P_i) and a dropout (D_i) layers (Fig. 6). The dropout layer has been added
 225 to prevent over-fitting by adding a step to remove some nodes. This significantly reduces overfitting and gives major improvements over other regularization methods [20]. The final architecture is a composition of elementary blocks.

Figure 6: The layers in an elementary block. It includes a CONV layer (red), a maximum POOL layer (yellow) and a DROP layer (green).

Fig. 7 illustrates the structure of the third architecture. For our purpose,
 230 we have assembled **3 elementary blocks** which are the main components of **EB-Net**. The parameters for each layer in each elementary block are described as below, the list of values follows the order of elementary blocks ($i = [1..3]$):

- CONV layers:
 - Number of filters: 32, 64, and 128
 - Kernel filter sizes: (3×3) , (2×2) , and (2×2)
 - Stride values: 1, 1, and 1
- POOL layers:
 - Kernel filter sizes: (2×2) , (2×2) , and (2×2)
 - Stride values: 2, 2, and 2
- DROP layers:
 - Probabilites: 0.1, 0.2, and 0.3

Three FC layers are the same as the second architecture: FC1 and FC2 have 1000 outputs, the last FC layer (FC3) has 16 outputs. As usual, a dropout layer is inserted between FC1 and FC2 with a probability equal to 0.5.

Figure 7: The architecture of EB-Net

The core of CNN is training over iteration. There are many ways to optimize the learning algorithm, but gradient descent [24] is currently a good choice to reduce the loss in neural network. The core idea is to follow the gradient until reaching a minimum of the cost function. So, we have chosen gradient descent in the backward phase to update the values of learnable parameters. The networks are designed to use the same learning rate and a momentum. The learning rate is initialized at 0.03 and stopped at 0.00001, while the momentum is updated from 0.9 to 0.9999. Their values are updated over training time to fit with the number of epochs ³ by applying parameters adjustment during the training. The three architectures implementations have been done on Lasagne framework [25] by Python code. More information about the model can be obtained from the repository on GitHub: <https://github.com/linhleavandlu/CNN.Beetles.Landmarks>

5. Experiments and results

This work is a part of a project about automatized morphology. The choice to turn to deep learning process has been motivated by the high difficulty to

³An epoch is a single pass through the full training set

segment some parts of the beetle images and consequently to apply classical image processing methods. The pronotum was the first part we have analyzed with deep learning. The networks have been trained in 5,000 epochs on Linux OS by using NVIDIA TITAN X cards. During the training, the images are
265 chosen randomly from the dataset with a ratio of 60% for training and 40% for validation. For each image, a set of 8 manual landmarks are available. They have been set by biologists and are considered as the ground truth for the evaluation. In deep learning, many kinds of loss expressions can be considered depending on the class of problem solving by the network, for example, Root Mean Square
270 Error (RMSE) is usually used for regression problems where the outputs are not discrete values. In the context of deep learning, landmark prediction can be seen as a regression problem because the coordinates of landmarks do not belong to discrete classes. Therefore, RMSE has been used to compute the losses of architectures during the training process.

Figure 8: The losses (training and validation) of the models

275 Fig. 8a shows the training errors and the validation errors during training phase of the first architecture. The blue curve presents the RMSE errors of training process while green curve is the validation errors. Clearly, over-fitting has appeared in the first model, i.e., training losses are able to decrease but

validation losses are stable. In the second model (Section 4), the parameters
of full-connected layers have been modified to prevent the over-fitting but it
seems that this solution is still not satisfying, the results are very similar to the
previous ones (over-fitting is still appears).

Fig. 9 illustrates the losses during the training of the third model, one can
note that after several epochs, the two-loss values become closed and the over-
fitting disappears. The sequence of Dropout addition inside elementary block
works well to prevent over-fitting and improve the accuracy of the model greatly.
This third model has been selected to compute automatically landmarks.

Figure 9: The losses (training and validation) of the third model

In order to extract predicted landmarks from all pronotum images, we have
applied *cross-validation* procedure to choose the test images, we call it *round*.
For each round, we have decided to choose 33 images for testing step. In order
to predict landmarks for all available images, we will do 9 rounds. The
remaining images are used as training and validation images. Of course, this
dataset will be augmented as described before to provide 1820 images for these
2 steps. Table. 1 resumes the losses of 9 rounds when we trained the third
model on pronotum images. Clearly, the training/validation loss among rounds
are tiny and stable.

Round	Training loss	Validation loss
1	0.00018	0.00019
2	0.00019	0.00021
3	0.00019	0.00026
4	0.00021	0.00029
5	0.00021	0.00029
6	0.00019	0.00018
7	0.00018	0.00018
8	0.00018	0.00021
9	0.00020	0.00027

Table 1: The losses during training the third model on pronotum images

To evaluate the coordinates of predicted landmarks, the correlation metrics between the manual landmarks and corresponding predicted ones have been computed. Table. 2 shows the correlation scores of 3 metrics (using *scikit-learn* [26]), e.g. coefficient of determination (r^2), explained variance (EV), and Pearson correlation. These three metrics are both appropriate for our dataset type. The results closed to 1 show that the predicted coordinates are very close with the ground truth. It proves that our prediction is good enough to replace manual landmarks in statistical analysis of pronotum morphology. However, standing on the side of image processing, seeing the real coordinates on images is more appropriate than statistical results. So, the distances (in pixels) between manual coordinates and predicted coordinates have been calculated for all images. Then, the average distance for each landmark has been computed.

Metric	r^2	EV	Pearson
Score	0.9952	0.9951	0.9974

Table 2: Correlation scores between manual landmarks and predicted landmarks

Table. 3 shows the average distances by landmarks on all images of pronotum dataset. With the images resolution 256×192 , we can consider that an error of 1% (corresponding to 2 pixels) could be an acceptable error. Unhappily, our

results exhibit average distance of 4 pixels in the best case, landmark 1 and more than 5 pixels in the worse case, landmark 6.

Landmark	Distance (in pixels)
1	4.002
2	4.4831
3	4.2959
4	4.3865
5	4.2925
6	5.3631
7	4.636
8	4.9363

Table 3: The average distances on all images per landmark on pronotum images.

Fig. 10 shows the distribution of the distances on the first landmark of all
 315 images. The accuracy based on the distance in each image can be separated into three spaces: best results, the images having distance less than the average value (4 pixels): 56.66%; acceptable results, the images having the distance from the average value to 7 pixels (standard deviation error): 31.40%; and the images which are clearly in error with the distance greater than 7 pixels: 11.94%.

Figure 10: The distribution of the distances on the first landmark. The blue line is the average value of all distances.

320 To illustrate this purpose, Fig. 11 shows the predicted landmarks on two test images. One can note that even some predicted landmarks (Fig. 11a) are closed

to the manual ones, in some case (Fig. 11b) the predicted ones are far from the expected results. So, the next step has been dedicated to the improvement of these results.

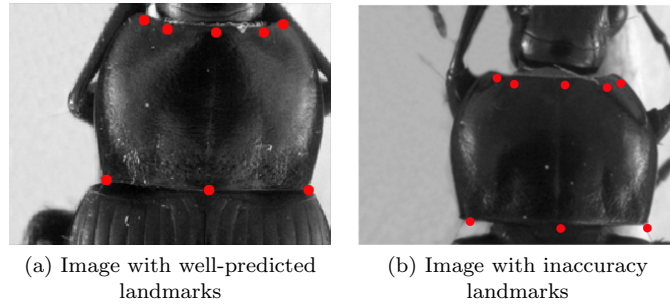

Figure 11: The predicted landmarks, in red, on the images in test set.

325 6. Improving results by fine-tuning

EB-Net, which was presented in Section 4, has been trained from scratch on five datasets of beetles (left mandible, right mandible, pronotum, elytra, and head). At this step, the network was able to predict the landmarks on the images. But as we have discussed before, even if the strength of the correlation
 330 seems to validate the results, when we display on the images, the predicted coordinates are not really closed to the manual ones, and the average distances are a little bit high.

Training a network from scratch is not the only way to work in Deep learning. It is possible to initialize parameter values by extracted values from another
 335 experiment on another dataset. It is called transfer learning [27]. Transfer learning addresses to re-use the gained parameters values after solving one problem, on a different but related problem. In tranfer learning, the obtained parameters values of a model, which have been used to solve a problem, are reused on other datasets [28]. The name of this procedure is currently called **fine-tuning**.

340 Fine-tuning does not only replace and retrain the last layer of the model on
the new dataset but also fine-tunes the weights of a trained model by continu-
ing the backpropagation. In this context, ImageNet [29] is a well-known dataset
with more than 100,000 images. It has been used to train many famous CNN
architectures such as AlexNet [6] or VGG-16 [22], which have encountered the
345 large success. The pre-trained models on ImageNet have been then shared in
deep learning community as a source to re-use features of ImageNet. Unfor-
tunately, some preliminary tests have shown that re-using ImageNet features
is not relevant for our application because landmarks detection has a distinct
difference from general object recognition, as mentioned in [30]. Furthermore,
350 we noticed that our problem is related to face recognition and facial key points
detection. So, we have decided to train EB-Net on a facial key points dataset
and then, the trained parameters have been transfered to fine-tune on beetle's
images.

6.1. Pre-train EB-Net on facial key points dataset

355 **Facial key points dataset** has been published as a challenge on Kaggle
community⁴. It includes 2,140 human face images with the size of 96×96 . Each
image contains 15 landmarks on the face: 6 landmarks for eyes, 4 landmarks for
eyebrows, 4 landmarks for mouth, and 1 landmarks for nose tip. Fig. 12 shows
four face images in the dataset and the landmarks on each face.

Figure 12: Four face images in the dataset and ground truth position of the landmarks.

⁴<https://www.kaggle.com/c/facial-key-points-detection>

360 For the pre-training step, EB-Net has been trained on facial key point dataset. The objective of this task is to evaluate and to compare the effectiveness of EB-Net and other published results in the challenge. Basically, the layer’s parameters are the same when training from scratch. We have just changed the input size of network model to 96×96 and the output of the last
365 FC layers to correspond to the number of landmarks (15 landmark). For hyper-parameters of model, the learning rate and momentum have been remained the same. However, the number of epochs has been changed to 10,000 instead of 5,000 to achieve better learning on the parameters. After training, the RMSE⁵ score that obtained is 1.1464. This score is better than top 3 on the leader
370 board of challenge. It proved that EB-Net fits perfectly with facial key points challenge and we have good reason to believe that the obtained parameter values of EB-Net on facial key points dataset can be used to fine-tune on beetle’s images.

6.2. Fine-tuning on each beetle’s part

375 EB-Net has been pre-trained on facial key points dataset with 30 outputs (15 landmarks \times 2 coordinates). Then, the parameters have been transfered to fine-tune on the images of each beetle’s part. The fine-tuning stage has been done by continuing the backpropagation to update the layers parameters.

In another scene, to be able to use the same parameters for fine-tuning
380 process, the input images have been cropped to suppress the part which is empty (background), to obtain a new image size of 192×192 ; and a modification was made on stride property of the first convolutional layer (changing from 1 to 2).

During fine-tuning, cross-validation has been applied to select data for training and validation. After finishing the fine-tuning process, EB-Net was used to

⁵RMSE: Root Mean Square Error

385 predict the landmarks on test images. To evaluate the accuracy of the model's output, the distances (in pixels) between predicted and corresponding manual landmarks have been calculated. Then, the average distances have been taken into account. Tables 4, 5, 6, 7, and 8 show the average distances by landmarks on each beetle's part of two processes: training from scratch and fine-tuning
390 process. **From scratch** columns remind the previously average distances when EB-Net was trained from scratch. **Fine-tune** columns present the new average distances after applying fine-tuning on each part. The green and red values represent the best and the worst average distances on each part. From these tables, there is a difference in average distances between two processes, the average distances of each landmark have decreased in the case of fine-tuning. It is clearly
395 proved that the quality of predicted landmarks with the help of fine-tuning is more better than training from scratch.

#LM	From scratch	Fine-tune
1	4.00	2.99
2	4.48	3.41
3	4.30	2.98
4	4.39	3.54
5	4.29	3.37
6	5.36	4.06
7	4.64	2.93
8	4.94	3.64

Table 4: Average distances comparison between training from scratch and fine-tuning on pronotum images

In order to get a better view of the results, we have considered that average values are hidden in different cases of errors. So, we have calculated other statistical indicators such as median, standard error, minimum value and maximum
400 values. All these statistical values are presented in Appendix A. From these tables, the minimum and the maximum distances have a large range of values. However, the median values, which separate the set into two parts, are very

17	8.29	4.57
18	8.89	5.89

Table 8: Average distances comparison between training from scratch and fine-tuning on left mandible images

close with minimum values and so far from maximum values, even smaller than
405 the mean distances. It confirms that almost distances stay around the median
values and the predicted landmarks are good enough to replace the manual ones.
Besides, the distribution of the distances on each landmark of each part have
been taken into account in Appendix B. We can observe that most of distances
are close to the mean and median values, only some exceptional cases are really
410 far. Fig. 13 shows the predicted landmarks of fine-tuning process in one case of
each part.

The fine-tuning process has improved the results of the proposed architecture
on both 5 datasets: left, right mandible, pronotum, elytra and head. All the
average distances have significantly decreased: $\approx 41.35\%$ on left mandible, \approx
415 46.51% on right mandible, $\approx 25.98\%$ on pronotum, $\approx 15.8\%$ on elytra, and
 $\approx 18.10\%$ on head part. Besides, if we consider a predicted landmark, which has
the distance (from manual ones) less than mean value plus standard deviation,
is acceptable, the accuracy of method on each part is **87.07%** on pronotum,
87.92% on head, **91.78%** on elytra, **93.58%** on left mandible and **88.31%** on
420 right mandible.

For segmentable images, we have a comparison between the results of deep
learning and early method where we have applied image processing techniques
to predict the landmarks [31]. Clearly, the result with fine-tuning has improved
the location of estimated landmarks. Even the average distances which obtained
425 from scratch training are still high but they are more stable than the results from
the early method: most of the average distance(or landmarks) of left mandibles
are less than the results of the early method, while the average distances are
very closed in the case of right mandibles.

7. Conclusion

430 In this work, we have presented how to apply CNN to predict the landmark
on 2D anatomical images of beetles. After going through many trial models,
we have presented EB-Net for automatic detection landmarks on anatomical
images of beetles which includes the repeated of some elementary blocks (an
elementary block consists of a convolutional layer, a max pooling layer, and a
435 dropout layer) followed by fully connected layers. Then, the proposed model
have been trained and tested by using two strategies: *train from scratch* and
fine-tuning.

In our case, the size of dataset is limited. Therefore, we have applied the
image processing techniques to augment dataset. The predicted landmarks have
440 been evaluated by calculating the distance between manual landmarks and cor-
responding predicted landmarks. Then, the average of distance errors on each
landmarks has been considered.

The results have been shown that using the convolutional network to predict
the landmarks on biological images leads to satisfying results without need for
445 segmentation step on the object of interest. The best set of estimated landmarks
has been obtained after a step of fine-tuning using the whole set of images that
we have for the project, i.e. about all beetle parts. The quality of prediction
allows using automatic landmarking to replace the manual ones.
