Abstract

In recent years, deep learning, which has been introduced in the middle of the previous century for artificial intelligence, has risen strongly because of improvements in the computation both in memory size and computing time with GPU programming. Deep learning, specially Convolutional Neural Network (CNN), has been applied to solve the problems in different domains such as computer vision, speech recognition, or languages translation, . . . In computer vision, CNN has been used to classify the images into different categories, or to detect the object in images/videos, or to predict the key points of the objects in the images, . . . and it has brought the amazing achievements. In this work, we propose a CNN model to predict the key points (landmarks) on 2D anatomical biological images, specify beetle's images. Our proposed network is trained and evaluated on a dataset includes the images of collecting from 293 beetles. During the experiments, the network is tested in two ways: training from scratch and applying fine-tuning. The quality of predicted landmarks is evaluated by comparing with the manual landmarks which provided by the biologists. The obtained results are considered to be statistically good enough to replace the manual landmarks for the different morphometry analysis.

1. Introduction

Key points (landmarks) detection has a wide useful in image analysis in different domain, such as: In geosciences, the key points can be used to recognize the seabed by extracting and comparing the landmarks from sonar images at different times; or computer vision, they are fundamental to detect the human face; in biology, the topography of the objects of an organism can be measured if we have enough the number of landmarks. Landmarks, or *key points*, or *points of interest*, are the points on the image that store important information about the shape of the object, *for example*, the left and right corners of eyes are two important points to detect the human eyes. Depending on the object, the number of landmarks may be different, as well as their position can be defined along the outline of the object or inside the object, i.e. the landmarks on *Drosophila* wings [1] are stayed on the veins of the wings, but the landmarks on human ears [2] can be located on the ear edge or inside the pinnae of the ears.

Early methods [3, 4, 5] mainly focused on the low level-vision of the image by applying the image processing techniques, and segmentation is most often the first and the most important step. This task remains a bottleneck to compute the features of an image. In some cases, the interested object is easy to extract and can be analyzed by applying the well-known image analysis procedures. Nevertheless, we can not apply the same procedure for un-segmentable images. It really becomes a challenge on the complex images. Luckily, the appearance of deep learning has seen huge success in handwritten digit recognition, speech, images classification and detecting objects in images. Now, an interesting thing is how to use deep learning for landmark detecting, which can be considered as the local characteristic of the image. Our motivation to design a CNN model that able to extract the landmarks on images (even it is segmentable or un-segmentable), which will be used to replace for the previous procedures.

The main idea consists of the designing and training a CNN [6] on a dataset with manual landmarks. Like other CNNs, the features are extracted by using a group of different layer types (i.e. convolutional layer, pooling layer,...).

After designing, the proposed model will be trained on the dataset includes the images which are taken from 293 beetles. For each beetle, the biologists have taken images of five parts: *left and right mandibles, head, elytra, and thorax* (Fig. 1). All the images are presented in the RGB color model with two dimensions. Along with each image, a set of landmarks has been marked by experts which can be used as ground truth to evaluate the predicted landmarks. During the experiments, the proposed network has been trained on the dataset by applying two strategies. In the first strategy, the network is trained from scratch on each dataset; while in the second strategy, the training process has been modified to include a fine-tuning [7] stage. Besides, the value of Root Mean Square Error (RMSE) is used to compute the loss during two experiment processes. For more information about the model, you can see at our repository on GitHub: https://github.com/linhleavandlu/CNN_Beetles_Landmarks.

The rest of this paper is organized as followed: Section 2 discusses the related works about determining the landmarks on 2D images. Then, a short overview about CNN and its components will be introduced in Section 3. Section 4 shows the procedure of designing the network model. Section 5 gives another approaches to augment the dataset. The first experiment of the network on each dataset is presented in Section 6. Section 7 presents a modification of training process and its experiment on datasets. Finally, the conclusion is given in Section 8.

2. Related works

In geometric morphometry, landmarks (or points of interest) are important features to describe the shape. Depending on the complicity of the objects in the image, setting automatic landmarks can rely on different methods. When the object can be segmented, the image processing techniques may applied to predict the landmarks. Lowe et al. [3] have proposed SIFT method to identify the keypoints on 2D images by extracting the distinctive features from the images. It is composed by four steps: (1) scale space extrema detection: a dif-

(a) Left mandible

(b) Right mandible

(c) Head

(d) Thorax

(e) Elytra

Figure 1: The anatomical images of beetle are taken into account.

ference of Gaussian (DoG) function is applied to identify the interested points at all scales; (2) keypoint localization: the keypoint candidates are localized and refined by deleting the points which have the low contrast or not localized along the edge; (3) orientation assignment: for each keypoint candidates, the orientation and gradient magnitude are computed by considering their 4-neighborhoods; (4) keypoint descriptor are computed for each keypoint from its orientation and gradient magnitude. From the descriptors of the keypoints, they can be used to find the corresponding points between two images. SURF is another method which has been proposed by Herbert Bay et al. [4]. The SURF algorithm is the same principles with SIFT but details in each step are different. This algorithm mainly has three steps: (1) keypoints detection, (2) local neighborhood description and (3) matching. Different with SIFT, SURF uses a blob detector base on the Hessian matrix to find the keypoints. The Hessian matrix is used as a measure of local change around the point and chooses the points where this determinant is maximal. Then, the descriptors are computed around the key points by describing the intensity distribution of keypoint's neighborhoods. The matching points from different images are obtained by comparing the descriptors of the key points. Palaniswamy et al. [5] have proposed a method to automatically detect the landmarks on 2D images of *Drosophila* wings (Fig. 2). The method is mainly based on probabilistic Hough Transform. It includes four steps: (1) features detection of the fly wing structure (segmentation); (2) using pairwise geometric histogram (PGH) to record the compact invariant shape descriptor; (3) estimating the global pose of wing using the probabilistic Hough transform; (4) and finally a template matching is applied to refine the correctly of individual features.

In recent years, deep learning [8] is known as a solution for the tasks in computer vision, especially for image analysis. Deep learning has been introduced in the middle of the previous century for artificial intelligence application but it has encountered several problems to take real-world cases. Luckily, the improvement of computing capacities, both in memory size and computing time with GPU programming, has opened a new perspective for deep learning. Many deep

Figure 2: A Drosophila wing and its landmarks

learning architectures have been proposed to solve the problems of classification [9, 10], image recognition [11, 12, 13], speech recognition [14, 15], language translation [16, 17], Using deep learning, specifically CNN, to predict the landmarks on 2D images has achieved better results even if the images that can not segment. Yi Sun et al. [18] have proposed a cascaded CNNs to predict the facial points on the human face. Their model includes the networks which have separated into three levels of the cascade. The networks recognize the human face from the global to the local view to increasing the accuracy of predicted key points. Zhanpeng Zhang et al. [19] proposed a *Tasks-Constrained Deep Convolutional Network* to optimize facial landmarks detection. Their model detected the facial landmarks with a set of related tasks such as head pose estimation, gender classification, age estimation, or facial attribute inference. Cintas et al. [2] has introduced a network to predict the landmarks on human ears (Fig. 3). After training, the network has the ability to detect 45 landmarks on human ears.

As an association with the biologist, we study to develop an automatic method for predicting the landmarks on beetle's anatomical (Fig. 1). As we can see in this section, the methods for landmarking can be divided into two groups by considering the techniques that they have used. Most of the methods in the first group choose the image processing techniques while other methods are used deep learning. In a previous work [20], we have applied a series of algorithms to detect the landmarks automatically on beetles mandibles which

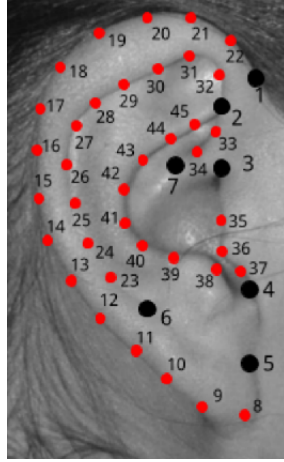

Figure 3: Landmarks on human ear in study of Cintas et al. [2]

are considered as the easiest objects to segment (with a quality enough good for our need). In that work, the landmarks have been detected by registering
115 two segmentations of images and then, using SIFT descriptor to refine the location of predicted landmarks. After the experiment, we have obtained good enough results on mandibles. Unfortunately, we have observed that the method did not provide good results when the segmentation is not precise, i.e. on thorax or elytra images. This is explained why we have turned the automatically
120 landmarking into another stage without any segmentation step. Using CNN for landmarking seems that a good choice for un-segmentable images.

3. Overview of Convolutional Neural Network

CNN is a feedforward network. It takes the information following one direction from the inputs to the outputs. Currently, CNNs have many different
125 variations, but in general, it consists of convolutional and pooling layers which are stacked together to convolve and to down-sample the input. Then, they are followed by one or more fully connected layers to give the decision as the output of the network.

Fig. 4 shows an example of a CNN for classification problem. The network

130 inputs directly an image to several stages of convolutional and pooling layers.
 Then, the representation is feed into one or more full connected layers. Finally,
 the last fully connected layer gives the category label for the input image. This
 architecture could be seen as a popular one that we can find from the literature.
 However, several architectures have been proposed recurrently to improve the
 135 accuracy or to decrease the computation costs. In this section, we will mention
 to the popular layers in a CNN: convolutional layers, pooling layers and fully
 connected layers.

Figure 4: A CNN network for classification problem

Convolutional layers: use as an features extractor by applying some learnable
 weights on the input images. The input image are convolved with the learnable
 140 weights in order to compute the new feature maps; then, the convolved results
 are sent through a nonlinear activation. In convolutional layer, the neurons
 are are arranged into feature maps. All the neurons within a feature map
 have constrained to be equal; however, different features maps within the same
 convolutional layer have different weights so that several features can be extract
 145 at each location of an input image.

Pooling layers: is mostly used to down-sampling the size of the input with
 the purpose to reduce the spatial resolution of the feature map to reduce the
 computation cost. Initially, it was common practice to use average pooling
 which propagates the average of all the input to the next layer. However, in
 150 more recent models [9, 10, 13], max pooling which propagates the maximum

value (selecting the largest value) with a receptive field to the next layer. Fig. 5 illustrates the differences between max and average pooling. Give an input image of size 4×4 , if applying a 2×2 filter and stride of two is applied, the output will be had the size of 2×2 for both cases. However, the value in each element of the output is different because the max pooling outputs the maximum values of the filter region, while average pooling outputs the average value of the same region.

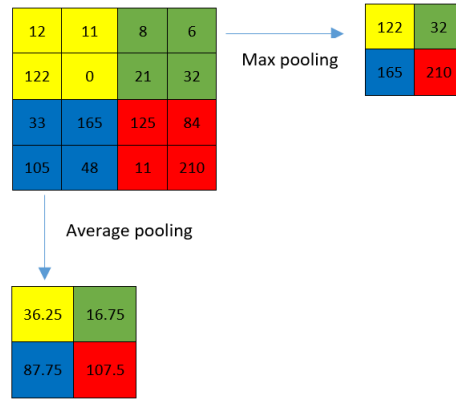

Figure 5: The results of different pooling

Fully connected layers: are usually follow the convolutional and pooling layer which used to extract the abstract feature representations. A CNN may be have one or more fully connected layers. It interprets the feature representations and perform a function of high-level reasoning (i.e. giving classification score) by applying the activation functions. In practice, the last fully connected layer refers to the output of the network and choosing the activation function is depended on which kind of problem that network solve, i.e. we usually softmax activation function for a classification problem but it is not useful in a support vector machine.

4. Network architectures designing

In the process, we have tried three network models before deciding the final architecture for detecting the landmarks on beetle images. Like other CNN models, we have employed the classical layers to construct the models, i.e., convolutional layers, maximum pooling layers, dropout layers and full-connected layers.

The first architecture is very classical one, it receives an image with the size of $(1 \times 192 \times 256)$ as the input. Then, the network consists on three repeated structure of a convolutional layers followed by a maximum pooling layers. Most CNNs, the hyperparameters of convolutional layers have been set to increase the depth of the images from the first layer to the last layer. That is reflected in the setting of the number of filters at each convolutional layer. So, the depths of convolutional layers increase from 32, 64, and 128 with different size of the kernels: (3×3) , (2×2) and (2×2) , respectively. Inserting pooling layers after a convolutional layers is a common periodcally. The pooling layer effects to progressively reduce the spatial size of the representation to reduce the number of parameters, computation in the network, and it also controls over-fitting. The operations of pooling layers independent on every depth slice of the input. The most common form is a pooling layer with filters of size (2×2) and a stride of 2. It downsamples every depth by 2 along width and height of the input. Therefore, all the kernels of maximum pooling layers have the same size of (2×2) with a stride of 2 as usual. At the end of the model, three full-connected layers have been added to extract the global relationship between the features and to procedure the outputs. The first of two full-connected layers are set to non-linearity to make sure these nodes interact well and take into account all possible dependencies at the feature level. The outputs of the full-connected layers are 500, 500 and 16. The output of the last full-connected layer corresponds to the coordinates $(x$ and $y)$ of 8 landmarks which we would like to predict. Fig. 6 shows details of the first model: The orange rectangles represent for convolutional layers while the yellow rectangles represent for maximum pooling

layers and three full-connected layers with their parameters are presented at the end of the model.

Figure 6: The architecture of the first model

The second architecture is modified from the first model. The layers are kept the same as the first one but the outputs of the first of two full-connected layers are changed from 500 (in the first model) to 1000 (Fig. 7). Increasing the value at full-connected layers is hoping to obtain more features from convolutional layer and to prevent the over-fitting.

Figure 7: The architecture of the second model

To build the third architecture, we have used the definition of *elementary block*. An elementary block is defined as a sequence of convolution (C_i), maximum pooling (P_i) and dropout (D_i) layers (Fig. 8). This significantly reduces overfitting and gives major improvements over other regularization methods [21]. The idea of dropout is to include some variations between different runs. During training phase, dropout samples are done from an exponential number of different “thinned” network. At test phase, it is easy to approximate the effect of averaging the prediction of all thinned networks by simply using a single unthinned network with smaller weights. So, we have modified the architecture by combining some *elementary blocks*.

Figure 8: The layers in an elementary block

Fig. 9 illustrates the layers in the third architecture. For our purpose, we
 215 have assembled **3 elementary blocks**. The parameters for each layer in each
 elementary block are as below, the list of values follows the order of elementary
 blocks ($i = [1..3]$):

- CONV layers:
 - Number of filters: 32, 64, and 128
 - Kernel filter sizes: (3×3) , (2×2) , and (2×2)
 - Stride values: 1, 1, and 1
 - No padding is used for CONV layers
- POOL layers:
 - Kernel filter sizes: (2×2) , (2×2) , and (2×2)
 - Stride values: 2, 2, and 2
 - No padding is used for POOL layers
- DROP layers:
 - Probabilites: 0.1, 0.2, and 0.3

Three full-connected layers (FC) are kept the same as the second architec-
 230 ture: FC1 and FC2 have 1000 outputs, the last full-connected layer (FC3) has
 16 outputs. As usual, a dropout layer is inserted between FC1 and FC2 with a
 probability equal to 0.5.

Figure 9: The architecture of the third model

The core of neural network is training over iteration. There are many ways to optimize the learning algorithm, but gradient descent [22] is currently a good choice to establish the way of optimizing the loss in neural network. The core idea is following the gradient until we statify with the results will remain the same. So, we have chosen gradient descent in the backward phase to update the values of learnable parameters and to increase the accuracy of the network. The networks are designed with a small sharing learning rate and a momentum. The learning rate is initialized at 0.03 and stopped at 0.00001, while the momentum is updated from 0.9 to 0.9999. Their values are updated over training time to fit with the number of epochs ². The implementation of the architectures have been done on Lasagne framework [23] by Python.

5. Data augmentation

A characteristic of machine learning and deep learning is using a volume dataset to train the model. Of course, we are not always have enough data for training in practice. One way to solve this problem is to create the fake data from real data and to add it to the training set. Dataset augmentation has been a particularly effective technique for a specific problem. For example, in images classification problem, the operations like translating, rotating or scaling the images have also effective. The fake images may be generated by translating (rotating or scaling) in each direction. Besides, injecting noise in the input can also see as a form of data augmentation.

Our dataset includes 293 images of beetles (for each anatomical part). All

²An epoch is a single pass through the full training set

the images are taken with the same camera in the same condition with a resolution of (3264×2448) . Each image has a set of manual landmarks provided by biologists, i.e, each thorax has 8 landmarks, each head has 10 landmarks. Applying CNNs to train each part with a small number of images to reach good results is impossible. So, we need to augment the dataset before training the networks. Firstly, we have found that the original solution of the images (3264×2448) are heavy for the neural network. For performance considerations, in most of CNNs [2, 6, 18], the size of the input is limited to (256×256) pixels, so we have decided to down-sampling the images to a new resolution (256×192) (to respect the ratio between x and y). Of course, the coordinates of manual landmarks have been also scaled to fit with the new resolution of the images. In usual way, the transformations have been used to augment the dataset (i.e rotation, translation, . . .) but the analysis of image by CNN is most often translation and rotation invariant. Therefore, two other procedures have been imaged to increase the number of images in the dataset (256×192) .

The first procedure is to change the value of a color channel in the original image to generate a new image. According to that, a constant is added to one of the RGB channels each time it is used for training. Each constant is sampled in a uniform distribution $\in [1, N]$ to obtain a new value caped at 255. For example, Fig. 10 shows an example when we added a constant $c = 10$ to each channel of an original image. Following this way, we can generate three version from an image.

Figure 10: A constant $c = 10$ has been added to each channel of an original image

In the second procedure, we have applied the opposite procedure to the first one. Instead of adding the value, we separate the channels of RGN into three gray-scale images as the network works on single channel images (Fig. 11).
 280 At the end of the processes, we are able generate six versions from an original image. In total, we have $293 \times 7 = 2051$ images for each anatomical part of beetle (an original image and six generated images). However, we have not used all images for training and validation. So, we have chosen 260 original images and their generations (1820 images) of each dataset for training and validation
 285 processes, the remaining images (33 original images) are used for test process.

Figure 11: Three channels (red, green, blue) are separated from original image

In practical, to obtain a fast convergence during the computing, it is useful to normalize the brightness of the images to $[0, 1]$ instead of $[0, 255]$ and the coordinates of the landmarks have been also normalized [22].

6. Experiments and results

290 Before widely applying to all anatomical parts, we have firstly tried with thorax part to evaluate the performance. The networks have been trained in 5,000 epochs on Ubuntu machine by using NVIDIA TITAN X cards. The set of images that used for training and validation are merged together. During the training, the images are chosen randomly from the dataset with a ratio of
 295 60% for training and 40% for validation. The training step takes into account a pair of information (*images, manual landmarks coordinates*) as training data.

In the context of deep learning, landmark prediction can be seen as a regression problem. So, we have used Root Mean Square Error (RMSE) to compute the loss of implemented architectures. At the test phase, images without landmarks are given to the trained network to produce output coordinates of the predicted landmarks. The results then evaluated by comparing with the manual landmarks coordinates provided by biologists which have been seen as ground truth.

Fig. 12 shows the training errors and the validation errors during traning phase of the first architecture. The blue curve presents the RMSE errors of training process while green curve is the validation errors. Clearly, over-fitting has appeared in the first model. The training losses are able to decrease but the validation losses are stable. In the second model (section 4), we have modified the parameters of full-connected layers to prevent the over-fitting but it seems that this solution is still not suitable.

Figure 12: The training and validation losses of the first model

Then, we have continued to train the third model on the same dataset of thorax images. Fig. 13 illustrates the losses during the training of the third model. Like the previous figure (Fig. 12), the blue line is training losses, the green line is validation losses. In the opposite with two previous models, the

315 losses are different (far) from the beginning but after several epochs, the values
become more proximate and the over-fitting problem has been solved. This
proves that adding dropout layers to build the elementary blocks have been
effects to prevent over-fitting and contributory improve the accuracy of the
model. *So, we have decided to keep the architecture of the third model for our*
320 *landmarking problem.*

Figure 13: The training and validation losses of the third model

In order to have the predicted landmarks for all thorax images (instead of
only 33 images), we have applied *cross-validation* to choose the test images,
called *round*. For each time, we have chosen a different fold of 33 images as
testing images, the remaining images are used as training and validation images
325 (293/33 \approx 9 rounds). Following that, the network will be trained with different
datasets, then the trained model will be used to predicted the lanmarks on the
images in the corresponding test set. Table. 1 resumes the losses of 9 rounds
when we trained the third model on thorax images.

To evaluate the coordinates of predicted landmarks, the correlation metrics
330 have been computed the correlation between the manual landmarks and their
corresponding predicted one. Table. 2 shows the correlation scores of 3 metrics
(using *scikit-learn* [24]), i.e, coefficient of determination (r^2), explained variance

Round	Training loss	Validation loss
1	0.00018	0.00019
2	0.00019	0.00021
3	0.00019	0.00026
4	0.00021	0.00029
5	0.00021	0.00029
6	0.00019	0.00018
7	0.00018	0.00018
8	0.00018	0.00021
9	0.00020	0.00027

Table 1: The losses during training the third model on thorax images

(EV), and Pearson correlation. All of three metrics have the same possibility. The best score is 1.0 if the correlation data is good, lower values are worse. It means that our predicted coordinates are very close with the ground truth. However, the measure is not enough good to provide a useful result to biologists. Moreover standing on the side of image processing, we are looking forward to seeing the predicted coordinates than the statistical results.

Metric	r^2	EV	Pearson
Score	0.9952	0.9951	0.9974

Table 2: Correlation scores between manual landmarks and predicted landmarks

The main goal of computing is to predict the coordinates of landmarks, so the distances (in pixels) between the coordinates of manual landmarks and corresponding predicted landmarks have been taken into account on all images. Then, the average of distances are computed by landmarks. Table. 3 shows the average distances by landmarks on all images of thorax dataset. With images of resolution 256×192 , we can consider that an error of 1% corresponds to 2 pixels that could be an acceptable error. Unhappily, our results exhibit

average distance of 4 pixels in the best case, landmark 1 and more than 5 pixels, landmark 6. Other error distances are more than 2% pixels.

Landmark	Distance (in pixels)
1	4.002
2	4.4831
3	4.2959
4	4.3865
5	4.2925
6	5.3631
7	4.636
8	4.9363

Table 3: The average distances on all images per landmark on thorax images.

Fig. 14 shows the distribution of the distances on the first landmark of all images. The accuracy based on the distance in each image can be separated into three spaces: the images have the distance less than average value (4 pixels): 56.66%; the images have the distance from average value to 10 pixels (5% acceptable errors): 40.27%; and the images have the distance greater than 10 pixels: 3.07%.

Figure 14: The distribution of the distances on the first landmark. The blue line is the average value of all distances.

To illustrate this purpose, Fig. 15 shows the predicted landmarks on two test
 355 images. One can note that even some predicted landmarks (Fig. 15a) are closed
 to the manual ones, in some case (Fig. 15b) the predicted ones are far from the
 expect results. This result explains why the average distance by landmarks are
 enough good while some predicted landmarks are so far from the manual one.
 So, the next step has been dedicated to the improvement of these results.

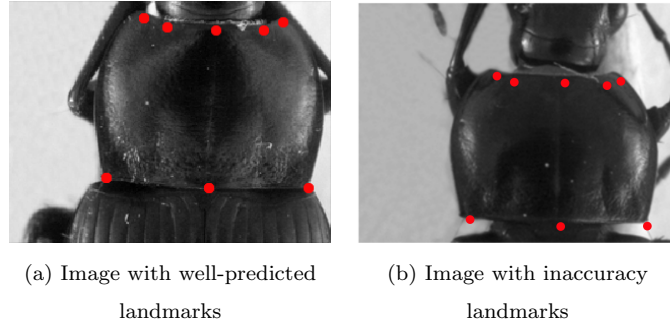

Figure 15: The predicted landmarks, in red, on the images in test set.

From the success of the third architecture on thorax dataset, we apply the
 360 same procedures (data augmentation, training, . . .) on other parts of beetle: *left*
and right mandibles, elytra and head. However, we have modified the number
 of output of the last full-connected layer to adapt with each dataset before
 training. According, the values at the last full-connected layer are set to 32,
 365 36, 22 and 20 outputs corresponds to 16, 18, 11 and 10 landmarks on left
 mandible, right mandible, elytra and head, respectively. Of course, we have also
 applied *cross-validation* to select testing data to get all predicted landmarks
 for all images in each dataset. Then, the quality of predicted landmarks are
 evaluated by comparing with the corresponding manual landmarks (distance
 370 computation). Table. 4 shows the average distances on each landmark of elytra,
 head, left and right mandibles anatomical, respectively. Comparing with the
 average distances on the thorax part, it seems that the proposed architecture
 provides more accurate predictions on the elytra dataset, but the results are
 opposite on other datasets.

Landmark	Distance (in pixels)			
	Right mandible	Left mandible	Elytra	Head
1	9.4981	9.1267	3.8669	5.528
2	7.1657	6.7198	3.973	5.1609
3	7.242	6.8704	3.9166	5.3827

Table 4: The average distances on all images per landmark on left mandible, right mandible, elytra and head images.

375 7. Resulting improvement by fine-tuning

The proposed network (third architecture) presented in Section 4 have been trained from scratch on five datasets of beetles (left mandible, right mandible, thorax, elytra, and head). At the first step, the network was able to predict the landmarks on the images. But as we have discussed, even if the strength
380 of the correlation seems to validate the results, when we display the predicted landmarks on the images, the quality of the predicted coordinates are also not enough precise, and the average error are also still high (of course, we have the distances are higher than the average distances).

In order to reach more acceptable results for biologists, we have broadened
385 model with another step of deep learning: **transfer learning**. That is a method enables to re-uses the model developed for a specific task/dataset to lead another task (called *target task*) with another dataset. This process allows rapid process and improves the performance of the model on the target task [25]. The most popular example has been given with the project ImageNet of Google [26] which
390 has labeled several millions of images. The obtained parameter values which can be used in another context to classify another dataset, eventually very different dataset [27]. The name of this procedure to re-use parameters to pretrain a model is currently called **fine-tuning**.

Fine-tuning does not only replace and retrain the model on the new dataset
395 but also fine-tunes the weights of a trained model by continuing the backpropagation. Unfortunately, some rapid tests have shown that re-using ImageNet features has not been relevant for our application. We have designed a way to reproduce the method with our own data. It is worth noting that of course the size of data to pre-train has drastically decreased. For our pre-training step, the
400 network has been trained on the whole dataset including the images of three parts of beetle *i.e thorax, elytra and head*. Then, the trained model has been used to fine-tune and test on each dataset.

7.1. Data preparation and training

The images training dataset is combined from the images of three sets: *thorax*, *elytra*, and *head* (after augmentation). When applying the training from the scratch, we have used cross-validation to select the data (9 folds). It means that for each dataset, we have some different training data and corresponding testing data. So, the images that use to train the model are just select from one of the folds in each dataset. Specifically, we have taken 1,820 images of each part. In total, it includes 5,460 images ($260 \times 7 \times 3$).

Figure 16: A presentation of head, thorax and elytra part with corresponding manual landmarks

However, another problem has been appeared when we combined the images from different dataset. That is the different number of landmarks on each part: 8 landmarks on thorax part, 10 landmarks on head part, and 11 landmarks on elytra part. Fig. 16 shows the position of the landmarks on each part. Because of the meaning of landmarks on each anatomical part for biologists, we cannot insert the landmarks arbitrary. So, we have decided to keep the landmarks on thorax as reference and to remove the landmarks on elytra and head parts instead of adding. We kept 8 (landmarks) as a reference number, then we have removed the supernumerary when it is unnecessary. Specifically, we have

420 removed three landmarks on the elytra part ($1^{st}, 6^{th}, 9^{th}$), and two landmarks on the head part ($5^{th}, 6^{th}$).

During training the proposed architecture on the combined dataset, the parameters of the network (learning rate, momentum, ...) are kept the same as training from scratch but the number of epochs are increased to 10,000 instead
 425 of 5,000 to achieve better learning on the parameters (weights). Additional, we have shuffled the training set. Because the neural network learns the faster from the most unexpected sample. It is advisable to choose a sample at each iteration that is the most unfamiliar to the system. Shuffling the examples will be helped the model works with different anatomical parts rather than the same
 430 anatomical samples in each training time.

7.2. Fine-tuning on each dataset

The combined dataset then used to train the third architecture with 16 outputs (8 landmarks). Then, the trained model is used to fine-tuning on each dataset. To compare the result with the previous one, we have also fine-tuned
 435 the trained model with different dataset by applying cross-validation. Firstly, we consider on the losses during fine-tuning. *For example*, Table. 5, 7, 9 show the losses during fine-tuning on thorax, elytra, and head dataset, respectively. Comparing with the losses when we trained the model from scratch, *i.e.* on thorax, the validation losses of all round in this scenario have been significantly
 440 decreased (around 40%).

On each part, the landmarks are predicted on the test images. Then, the average error based on the distances between predicted and corresponding manual landmarks have been also computed. Table. 6, 8, 10, 11, and 12 show the average distances per landmark on thorax, elytra, head, left and right mandibles
 445 dataset, respectively. **From scratch** columns remind the previously average distances. **Fine-tune** columns present the new average distances after applying fine-tuning on each part. It is clearly shown that the result of predicted landmarks with the help of fine-tuning is more precise than training from scratch. For example, the average distance at each landmark has decreased. Additional,

450 when comparing the average distances between two processes, the worse case of fine-tuning process is still better than the best case of training from scratch.

Table 12: The average error distance per landmark of two processes on head images

(a) Left mandible

(b) Right mandible

(c) Head

(d) Elytra

(e) Thorax

Figure 17: The distribution of average distances on each landmark of each beetle's anatomical

average distances are significantly decreased. Specially, the results have been
465 improved $\approx 26.9\%$ on left mandible, $\approx 22.8\%$ on right mandible, $\approx 40.3\%$ on
thorax, $\approx 39.8\%$ on elytra, and $\approx 46.4\%$ on head part based on considering
the average distances per landmark. Addition, in the cases of thorax and head
part, even if we plus the average distance and its standard deviation, the results
are also less than the result when we trained the model from scratch. For
470 segmentable images, we have a comparison between the results of deep learning
and early method where we have applied image processing techniques to predict
the landmarks. Clearly, the result with fine-tuning have improved the location
of estimated landmarks, even when the average distances are still high when we
trained the model from scratch: most of the average distance(or landmarks) of
475 left mandibles are less than the results of the early method, while the average
distances are very closed in the case of right mandibles.

To illustrate the final results, we display the distribution of the distances in
both cases: the best and the worst results (resp. landmark 1 and 6 on thorax
dataset) of five datasets (thorax, elytra, head, left and right mandible) in Fig.
480 18, 19, 20, 21, and 22, respectively. In these figures, the left images present
for the results when we trained the model from scratch; while the right images
shows the results after applying fine-tuning. The blue lines in the charts present
the average distance values. Clearly, the results in the fine-tuning case have been
improved significantly than training from scratch.

Figure 19: The distribution of distances on 1st and 8th landmarks of all images in two testing steps (CNN and fine-tuning) (on **elytra** dataset).

Figure 20: The distribution of distances on 1st and 6th landmarks of all images in two testing steps (CNN and fine-tuning) (on **head** dataset).

Figure 21: The distribution of distances on 1st and 4th landmarks of all images in two testing steps (CNN and fine-tuning) (on **left mandible** dataset).

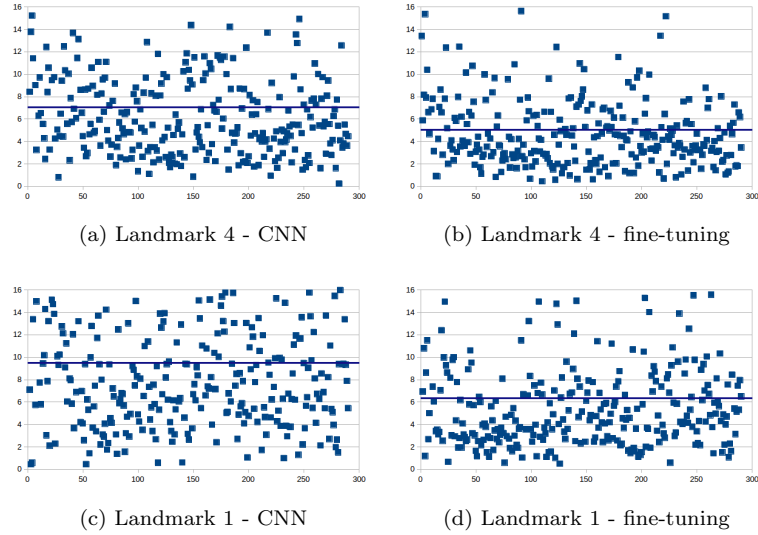

Figure 22: The distribution of distances on 1st and 4th landmarks of all images in two testing steps (CNN and fine-tuning) (on **right mandible** dataset).

485 8. Conclusion

In this work, we have presented how to apply convolutional neural network to predict the landmark on 2D anatomical images of beetles. After going through many trial models, we have presented a convolutional neural network for automatic detection landmarks on anatomical images of beetles which includes
490 the repeated of some elementary blocks (an elementary block consists of a convolutional layer, a max pooling layer, and a dropout layer) followed by fully connected layers. Then, the proposed model have been trained and tested by using two strategies: *train from scratch* and *fine-tuning*.

In our case, the size of dataset is limited. Therefore, we have applied the
495 image processing techniques to augment dataset. The predicted landmarks have been evaluated by calculating the distance between manual landmarks and corresponding predicted landmarks. Then, the average of distance errors on each landmarks has been considered.

The results have been shown that using the convolutional network to predict
500 the landmarks on biological images leads to satisfying results without need for segmentation step on the object of interest. The best set of estimated landmarks has been obtained after a step of fine-tuning using the whole set of images that we have for the project, i.e. about all beetle parts. The quality of prediction allows using automatic landmarking to replace the manual ones.
